HASHLIB

Industry-Standard Cryptography on the TI-84+ CE

Version 9.2

Quick Reference

by Anthony Cagliano

Contents

Installation

`HASHLIB` is a library, not a program or an application. It is meant to be used in accordance with the same usage guidelines as the other libraries in the CE C toolchain (by MateoC). If you are a developer looking to use the library within your own project, you must follow the steps below. *NOTE: This assumes you have defined the shell variable `$CEDEV` as directed by the CE C toolchain documentuation. If you have not done this (or familiarized yourself with the toolchain documentation), I recommend doing so first before attempting to use this (or any other) library.*

- Move the library's C header and .lib files to the correct directories. This is `$CEDEV/include` for `hashlib.h` and `$CEDEV/lib/libload/` for `hashlib.lib`. You can do this manually, or by running `make install` in a Terminal window from within the directory containing this documentation file.
- Include the C header for HASHLIB in any C source file where you use anything from the library. Do this like so: `#include <hashlib.h>`.
- Use defines or functions from the library freely within any C source file where the library's header is included.

If you are an end user who needs the library present, either for testing or for using a program that requires HASHLIB, install it by sending the library file, the TI application variable `hashlib.8xv` to your device. If you do not do this, programs that use it will fail to start, instead returning to the homescreen and yelling at you about a missing library.

1 Enumerations, Definitions, and Macros

Hash Algorithms	
Identifier	**Algorithm**
SHA256	Selects the SHA-256 hash or hmac algorithm

AES Cipher Modes	
Identifier	**Description**
AES_MODE_CBC	Selects cyclic-block chaining (CBC) cipher mode
AES_MODE_CTR	Selects counter (CTR) cipher mode

AES Padding Schemes	
Identifier	**Description**
SCHM_DEFAULT	Enables default padding mode (PKCS#7)
SCHM_PKCS7	Enables the PKCS#7 padding scheme
SCHM_ISO2	Enables the ISO-9797 M2 padding scheme

AES Response Codes	
Identifier	**Description**
AES_OK	AES operation completed w/o errors
AES_INVALID_ARG	One or more inputs invalid
AES_INVALID_MSG	Message cannot be encrypted
AES_INVALID_CIPHERMODE	Cipher mode not supported
AES_INVALID_PADDINGMODE	Padding mode not supported
AES_INVALID_CIPHERTEXT	Ciphertext cannot be decrypted

RSA Response Codes	
Identifier	**Description**
RSA_OK	RSA operation completed w/o errors
RSA_INVALID_ARG	One or more inputs invalid
RSA_INVALID_MSG	Message value exceeds modulus value
RSA_INVALID_MODULUS	Modulus not odd Length not in range 128-256 bytes
RSA_ENCODING_ERROR	OAEP requirements not met, ex: Message not less than twice the hash digest length plus two.

Constant Definitions	
Identifier	**Description**
fastRam_Safe	Region of fast RAM generally safe to use for short-term computations
fastRam_Unsafe	Region of fast RAM used by this library for PRNG and hashing speed
SHA256_DIGEST_LEN	Binary length of SHA-256 hash digest (32 bytes)
AES_BLOCKSIZE	Block length of the AES cipher (16 bytes)
AES_IVSIZE	Length of the AES initialization vector (same as block size)

Macros	
Identifier	**Description**
aes_outsize(len)	Returns the smallest multiple of the block size that can hold the ciphertext with any required padding
aes_extoutsize(len)	Returns the output of `aes_outsize(len)` with an additional 16 bytes added for the IV

2 Implementations

2.1 Cryptographically-Secure Random Number Generator (CSRNG)

Many of the pseudo random number generators (PRNGs) you find in computers, even the one within the C toolchain for the CE, are insecure for cryptographic purposes. They produce statistical randomness, but the state is generally seeded using a value such as rtc_Time(). If an adversary reconstructs the seed, every output of the PRNG becomes computable with little effort. These types of PRNGs are called deterministic algorithms–given the input, the output is predictable. These PRNGs work for games and other applications where the illusion of randomness is sufficient, but they are not safe for cryptography.

The pseudo random generator provided by HASHLIB is a hardware-based RNG (HWRNG) that derives entropy (unpredictability) by reading from bus noise into a pool of sufficient size to produce enough entropy to generate a 32-bit number. That pool is compressed into a 32-bit number using a cryptographic hash. These mechanisms together ensure that the PRNG satisfies all constraints for cryptographic security. For more details see *HASHLIB Cryptanalysis, Section 1.*

bool csrand_init(void)

Initializes the CSRNG by polling the 512 bytes from 0xD65800 to 0xD66000 looking for a floating bit within unmapped memory with the least bias. Returns **True** if the source selection succeeded and **False** if it failed. Be sure to intercept and handle a return value of False from this function.

uint32_t csrand_get(void)

Returns a securely pseudo random 32-bit (4 byte) unsigned integer.

bool csrand_fill(void* buffer, size_t size)

buffer Pointer to an arbitrary buffer to fill with random bytes.
size Number of bytes to write.

2.2 Cryptographic Hashing

A cryptographic hash is a fixed-size representation of an arbitrary-length stream of data. The main function of a cryptographic hash is to verify whether some block of stored or transmitted data has changed from its original creation. This works because the deviation of even a single bit in the input changes the hash quite drastically.

Hashes have a number of practical uses, not just in cryptography but throughout the field of information security. A few of these uses are:

- **File integrity monitoring**: A database of hashes for known good files is saved and consistently checked against the current state of a system. Changes to the current hashes can reveal potentially malicious tampering with files.
- **Data transfer integrity**: Including a hash with data sent over the Internet can have a number of benefits. Firstly, if packets are lost between the source and destination, a mismatch between the included hash and one computed by the destination would reveal the transfer as corrupted and then a well-designed transmission control protocol would initiate a re-transmission. A similar benefit is in the detection of malicious tampering of the message in transit. It is not possible to differentiate between packet loss and malicious tampering, and so any message that fails a transfer integrity check should never be accepted.
- **Password encryption**: Hashes are used to encrypt passwords as well; However the class of hashes

to which those belong are vastly different. Cryptographic hashes are fast and efficient algorithms for dealing with streams of data quickly but are (for that very reason) insecure for encrypting passwords. While cryptographic hashes are involved in some moderately-secure key derivation functions, such as PBKDF2, long-term storage of passwords requires the use of a **slow hash** like `bcrypt` or `argon`. These hash algorithms have certain characteristics that make them safer for encrypting passwords. Sadly, HASHLIB does not (yet) implement any password hashing algorithms.

void hash_init(hash_ctx* ctx, uint8_t hash_alg)

Initializes the hash-state context for use.
ctx A pointer to an instance of *hash_ctx*.
hash_alg The hashing algorithm to use. See `hash_algorithms` (Enumerations).

void hash_update(hash_ctx* ctx, const void* data, size_t len)

Updates the hash-state with new data. Be sure to initialize it first!
ctx A pointer to an instance of *hash_ctx*.
data A pointer to arbitrary data to hash.
len The size, in bytes, of the data to hash.

void hash_final(hash_ctx* ctx, void* digest)

Performs final transformations on the context and returns a digest from the current hash-state.
Does not destroy the context. It can still be used with the same data stream if needed.
ctx A pointer to an instance of *hash_ctx*.
digest A pointer to a buffer to write the digest to.

2.3 Hash-Based Message Authentication Code (HMAC)

An HMAC generates a more secure hash by using a key known only to authorized parties as part of the hash initialization. Thus, while normal hashes can be generated and verified by anyone, only the parties with the key can generate and validate using a HMAC hash. An HMAC can fill the same roles as a normal cryptographic hash, but provides endpoint validation as well.

void hmac_init(hmac_ctx* ctx, const void* key, size_t keylen, uint8_t hash_alg)

Initializes the HMAC hash-state context for use.
ctx A pointer to an instance of *hmac_ctx*.
key A pointer to the key to use in the HMAC initilaization.
keylen The length of the key, in bytes.
hash_alg The hashing algorithm to use. See `hash_algorithms` (Enumerations).

> NIST recommends a minimum **key** length of 128 bits, or 16 bytes.

void hmac_update(hmac_ctx* ctx, const void* data, size_t len)

Updates the HMAC hash-state with new data. Be sure to initialize it first!
ctx A pointer to an instance of *hmac_ctx*.
data A pointer to arbitrary data to hash.
len The size, in bytes, of the data to hash.

void hmac_final(hmac_ctx* ctx, void* digest)

Performs final transformations on the context and returns a digest from the current hash-state.
Does not destroy the context. It can still be used with the same data stream if needed.
ctx A pointer to an instance of *hmac_ctx*.
digest A pointer to a buffer to write the digest to.

2.4 Mask and Key Generation

Sometimes in cryptography you need to generate hashes or keys of an arbitrary size. Two related, but different, functions exist to fill this role. The first of the two is a **mask generation function (MGF)**. A MGF generates a mask of arbitrary length by passing the data with a counter appended to it to a cryptographic primative such as SHA-256. The second of the two is a **password-based key derivation function**. A PBKDF works by using the supplied password as the key for an HMAC and then hashing the salt for the given number of rounds for each block of output.

void hash_mgf1(const void* data, size_t datalen,
void* outbuf, size_t outlen, uint8_t hash_alg)

Generates a mask of a given length from the given data.
data A pointer to data to generate the mask with.
datalen The length, in bytes, of the data.
outbuf A pointer to a buffer to write the mask to.
outlen The number of bytes of the mask to output.
hash_alg The hashing algorithm to use. See `hash_algorithms` (Enumerations).

void hmac_pbkdf2(const char* password, size_t passlen,
void* key, size_t keylen
const void* salt, size_t saltlen,
size_t rounds, uint8_t hash_alg)

Generates a key of given length from a password, salt, and a given number of rounds.
password A pointer to a string containing the password.
passlen The length of the password string.
key A pointer to a buffer to write the key to.
keylen The number of bytes of the key to output.
salt A pointer to a buffer containing psuedorandom bytes.
saltlen The length of the salt, in bytes.
rounds The number of times to iterate the HMAC function per block in the output.
hash_alg The hashing algorithm to use. See `hash_algorithms` (Enumerations).

> NIST recommends a minimum **salt** length of 128 bits, or 16 bytes.

2.5 Advanced Encryption Standard (AES)

The **Advanced Encryption Standard (AES)** is a symmetric encryption system and a block cipher. Symmetric encryption means that the same key can be used for both encryption and decryption. A block cipher is a cipher in which the data is operated on in blocks of a fixed size. For AES this block size is 16 bytes or 128 bits. AES is one of the most secure encryption systems in use today, expected to remain secure even through the advent of quantum computing. It is also fast and more secure than asymmetric encryption for smaller key sizes.

aes_error_t aes_init(const aes_ctx* ctx, const void* key, , size_t keylen, uint8_t ciphermode)

Configures an AES context given a key and ciphermode.
ctx Pointer to an AES key schedule to output.
key Pointer to a buffer containing the AES key.
keylen The length, in bytes, of the AES key.
ciphermode The mode of operation the cipher should use. Accepts: `AES_MODE_CBC` or `AES_MODE_CTR`.

If **AES_MODE_CBC** is passed as the cipher mode, then padding is enabled and **SCHM_DEFAULT** will be set internally. This sets the PKCS#7 padding scheme. If you wish to change this, the other available padding mode is **ISO-9797 M2**. You can change the padding mode by setting the field after calling `aes_init`.

```
aes_ctx ctx;
aes_init(&ctx, key, keylen, AES_MODE_CBC);  // sets padding mode SCHM_PKCS7
ctx.padding_mode = SCHM_ISO2;  // want to change padding mode?
```

If **AES_MODE_CTR** is passed as the cipher mode, padding is disabled and altering the above will have no effect. CTR mode slightly alters the functionality of the initialization vector passed to `aes_encrypt` and `aes_decrypt`. By default, the first 8 bytes (64 bits) of the IV are a fixed nonce which should be securely pseudo random. The last 8 bytes (64 bits) of the IV are a counter, which can (but need not) be initialized to a random value or simply set to 0. To change this behavior, you can specify the length of the counter by setting that field within the context:

```
aes_ctx ctx;
aes_init(&ctx, key, keylen, AES_MODE_CTR);  // sets counter len 8
ctx.ctr_counter_len = 4;  // want to change counter len?
```

Whatever value you set here will be the length of the counter, and whatever remains of the IV will be used as the fixed-length nonce. Valid counter lengths are from 1 to the block size.

The size of your counter in CTR mode directly impacts the size of the stream you can encrypt before the IV cycles, and the cipher begins leaking information. Leaving the default behavior is recommended.

Ciphers begin leaking data after the same key is used on a certain amount of data. For AES it is recommended that you cycle your key after encrypting 2^{64} blocks of information.

aes_error_t aes_encrypt(const void* plaintext, size_t len, void* ciphertext, const aes_ctx* ks, const void* iv)

Encrypts the given message using the AES cipher.
ctx A pointer to an AES cipher configured by aes_init().
plaintext A pointer to a buffer containing data to encrypt.
len The length of the data to encrypt.
ciphertext A pointer to a buffer to write the encrypted output to.
iv A pointer to an initialization vector, a buffer equal to the block size containing pseudo random bytes.

Generate a new **IV** for each message.
Ciphertext should be equal in size to the smallest multiple of the blocksize that can hold the encrypted data and any necessary padding. Helper macros provided.

aes_error_t aes_decrypt(const void* ciphertext, size_t len, void* plaintext, const aes_ctx* ks, const void* iv)

Decrypts the given message using the AES cipher.
ctx A pointer to an AES cipher configured by aes_init().
ciphertext A pointer to a buffer containing data to decrypt.
len The length of the data to decrypt.
plaintext A pointer to a buffer to write the decrypted output to.
iv A pointer to an initialization vector, a buffer equal to the block size containing pseudo random bytes.

> Decrypt using the same **IV** that the message was encrypted with.

2.6 RSA Public Key Encryption

Public key encryption is a form of asymmetric encryption generally used to share a secret key for AES or another symmetric encryption system. To communicate between two parties, both need a public key and a private key. The public key is (hence the term "public") common knowledge and is sent to other parties in the clear. The private key is known only to the host. The public key is used to encrypt messages for the host, and the private key is used by the host to decrypt those messages. The public key and private key are inverses of each other such that:
$encrypted = message^{\,public\ exponent} \% public\ modulus$
$message = encrypted^{\,private\ exponent} \% private\ modulus$
RSA is very slow, especially on the TI-84+ CE. Encrypting with just a 1024-bit modulus will take several seconds. For this reason, do not use RSA for sustained encrypted communication. Use RSA once to share a key with a remote host, then use AES. Also the RSA implementation in this library is encryption only. This means you will need to handshake with a server to create a secure session, like so:

(a) Connect to remote host. Let that server generate a public and private key pair. Send the public key to the calculator.

(b) Use hashlib to generate an AES secret. Encrypt that secret using RSA and send the encrypted message to the remote host.

(c) Decrypt the message on the server, and set up an AES session using the secret just shared with the remote host.

rsa_error_t rsa_encrypt(const void* msg, size_t msglen, void* ciphertext, const void* pubkey, size_t keylen, uint8_t oaep_hash_alg)

Encrypts the given message using the given public key and the public exponent 65537.
Applies the OAEP v2.2 encoding scheme prior to encryption.
msg A pointer to a buffer containing data to encrypt.
msglen The length of the data to encrypt.
ciphertext A pointer to a buffer to write the encrypted output to.
pubkey A pointer to an RSA public modulus.
keylen The length of the RSA public modulus, in bytes.
oaep_hash_alg The hashing algorithm to use for OAEP. See `hash_algorithms` (Enumerations).

2.7 Miscellaneous Functions

void digest_tostring(const void* digest, size_t len, const char* hexstr)

Outputs a textual representation of the hex encoding of a binary digest.
Ex: 0xfe, 0xa4, 0xc1, 0xf2 => "FEA4C1F2"
digest A pointer to a digest to convert to a string.
len The length of the digest, in bytes, to convert.
hexstr A pointer to a buffer to write the string. Must be equal to twice the digest length + 1.

void digest_compare(const void* digest1, const void* digest2, size_t len)

Compares the given number of bytes at *digest*1 with *digest*2 in a manner that is resistant to timing analysis.
digest1 A pointer to the first buffer to compare.
digest2 A pointer to the second buffer to compare.
len The number of bytes to compare.

2.8 Addendum: Authenticated Encryption with HASHLIB

While HASHLIB provides no implemented authenticated encryption schemes, it is possible to construct one using the provided API. This section will explain how to do so, review some rules for constructing one properly (as well as some pitfalls that can arise) and give an example that uses the existing API.

Authenticated encryption is an encryption scheme that combines a cipher with a cryptographic hash, producing a data stream that is not only obfuscated but also has its integrity and authenticity verifiable. The aforementioned hash is usually appended to the end of the data stream and is the output of passing the entire data stream (encrypted and unencrypted portions) to the hashing algorithm. Using a cryptographic hash like SHA-256 will ensure ciphertext integrity but not authenticity. An HMAC can ensure both integrity and authenticity since it incorporates a key that you can exchange with authorized parties, allowing only those parties to authenticate the message.

Rules for implementing authenticated encryption properly:

(a) **Use different keys for encryption and authentication. Do not interchange them.**

(b) **Generate new keys for each secure session. Never reuse keys.**

(c) **Encrypt, then authenticate. Run your message through the cipher first, then hash the output. This method is more secure.**

(d) **Hash the entire message, encrypted and unencrypted portions.** Just because a segment of a message doesn't need to be hidden doesn't mean we shouldn't check for tampering.

Sample authenticated encryption construction using HASHLIB API

```
// assume data in ‘message‘, header in ‘header‘
char packet[200];  // this can be smaller or larger, as needed
uint8_t cipher_key[32];  // this can be 16, 24, or 32 for AES
uint8_t hmac_key[32];   // this is arbitrary, can be any size >=16
aes_ctx ctx;
hmac_ctx hmac;

// generate AES key, HMAC key, and IV
if(!csrand_init()) return 1; // handle this. Always handle this.
csrand_fill(cipher_key, sizeof cipher_key);
csrand_fill(hmac_key, sizeof hmac_key);
csrand_fill(&packet[sizeof header], AES_BLOCKSIZE);

// copy message and headers into place. Packet format [headers][IV][message]
memcpy(packet, header, sizeof header);
memcpy(&packet[AES_BLOCKSIZE + sizeof header], message, sizeof message);

```

```
18      // initialize AES key schedule and encrypt message
19      aes_init(&ctx, key, 32, AES_MODE_CTR);
20      aes_encrypt(&ctx, &packet[AES_BLOCKSIZE + sizeof header], sizeof message, &packet[
            AES_BLOCKSIZE + sizeof header], &packet[sizeof header]);
21
22      // append HMAC to message. Packet format [headers][IV][message][hmac]
23      hmac_init(&hmac, hmac_key, sizeof hmac_key, SHA256);
24      hmac_update(&hmac, packet, sizeof headers + sizeof message + AES_BLOCKSIZE);
25      hmac_final(&hmac, &packet[sizeof headers + sizeof message + AES_BLOCKSIZE]);
```

4 Disclaimer

HASHLIB is a work-in-progress and has seen very little time as the forerunning cryptography library for the TI-84+ CE calculator. This means that it has not had much time to be thoroughly analyzed, and due to some hardware constraints may never offer total security against every possible attack. For this reason, I heavily advise that however secure HASHLIB may be, you never use it for encrypting truly sensitive data like online banking and other accounts, credit card information, and the like over an insecure network. It is likely safe enough to be used to encrypt data transfers and account login for TI-84+ CE game servers and package managers like the ones currently under development. By using this software you release and save harmless its developer(s) from liability for data compromise that may arise should you use this software.
